Introduction

The goal of this exercise was to perform some basic processing steps of raw measurement data from a met mast. The data used here originates from the FINO 1 platform in the German North-Sea which includes two wind vanes at heights of $33m$ and $90m$ as well as eight anemometers at heights $33m, 40m, 50m, 60m, 70m, 80m, 90m$ and $100m$. The given time period of 1-Hertz data is of one month (January 2013). The six tasks described in the following reach from standard data treatment to a first simple analysis by looking at the increment probability density function in terms of wind speed fluctuations.

1 Importing Data into Matlab

The first step was loading the data given as ASCII file into Matlab-readable data structures. For the first task we used the function `readtable()` to import the data with the corresponding delimiter as parameter. The advantage of using a table structure instead of a matrix is that the column headers like 'u100' or 'Time' are stored within the data structure. In this way we can easily separate the actual measurement data from the time stamp by splitting the table up in two matrices.

```
1 time_stamp = raw_data{:, {'Time'}};
  raw_data = raw_data{:, {'d90', 'd33', 'u100', 'u90', 'u80', ...
3  'u70', 'u60', 'u50', 'u40', 'u33'}};
```

2 Marking invalid data

In order to mark invalid data which is provided with a value of -999 by the measurement system the next section of our Matlab script converts all values -999 to *NaN*. Matlab checks if there is any invalid Data and replaces it with *NaN*. This is necessary for some remaining tasks when means and standard deviations will be computed which must not consider invalid values.

```
1 raw_data(raw_data==-999) = NaN;
```

3 Generating a continuous time axis

To avoid gaps in the time axis we first converted our time t with *datenum()* to a numeric value. The numeric values represent elapsed time in units of days. Hence, 1 second corresponds to the fraction of $\frac{1}{24 \cdot 60 \cdot 60}$ of these numeric values. So after multiplication with the inverse value of that and rounding we obtain unique integer IDs for every occurring time-stamp. Afterwards, we created the continuous time axis, by initializing a vector with length equaling exactly the number of seconds in January. Then, we filled the corrected data matrix *data_pp* with *NaN* values and overwrote this matrix with our existing data at all indexes where values are given.

```
1 t = (datenum(time_stamp, 'yyyy-mm-dd HH:MM:SS'));
   clear time_stamp;
3 t = round(t*24*3600);
   last_time = 31*24*3600;
5 tnew=[1:1:last_time]';
   n = length(tnew);
7 data_pp = NaN(length(tnew),10);
   for i = 1:length(raw_data(:,1))
9       data_pp(t(i)-t(1)+1, :) = raw_data(i, :);
   end
11 time = (1:length(data_pp))';
   data_pp = [time, data_pp];
```

4 Computing 10min means and standard deviations

This task is a first step of statistical analysis of the given data. We split our time axis into intervals of 600 seconds and for each interval we computed the mean and standard deviation for all ten variables. Invalid data can be ignored by using the commands *nanmean()* and *nanstd()*. Considering the wind directions a special treatment of the angles is required in order to handle the circular data, e.g. the mean value of 350° and 10° is not 180° but 0°. Some trigonometric functions can be employed in order to cope with this. We plotted the ten minute means of the *u90* anemometer for one specific day and added the standard deviation to it. The outcome is depicted in figure 1.

For this specific day we observe a very strong fluctuation of the wind over the day. During the early morning the wind is steadily strong with windspeeds greater then 20m/s then drops by almost 60% until 8 am, then picks up again to reach a maximum of around 24m/s in the evening.

Figure 1: 10 minute intervals for Jan 30th 2013

Indeed a very stormy day. The mean value and standard deviation are obviously not stationary because then mean is high in the morning and evening and low in between. The fluctuations and thus the standard deviation picks up in the evening and therefore is also not stationary.

5 Extreme values

In this task we looked for so called spikes. These are extremely high or low values within their immediate neighborhood, here 10 minutes intervals. A standard procedure to define spikes is to find values which exceed $[\mu - 5\sigma, \mu + 5\sigma]$ in these intervals where μ is the mean and σ is the standard deviation.

Two such intervals and contained spikes were found by our algorithm and are plotted in Figures 2a and 2b. The first shows a spike which appears to be of unphysical nature due to a relatively monotonous behavior with only small fluctuations except one single value. This single value is

below the $\mu - 5\sigma$ line. So here we could talk of a measurement error. The second plot however exhibits a more physical behavior. Here we have stronger fluctuations overall and the spike which is below $\mu - 5\sigma$ matches the fluctuational pattern because the values before and after the spike also deviate a lot from the mean over a considerable period of time. Regarding wind measurements the standard deviations is not a constant attribute but also varies over time. Especially in the field of wind measurement we have high fluctuations in the area of 1 second and less. The magnitude of the standard deviation always depends on the mean value and therefore the 5σ criterion provides different quality at different conditions, different sites and different times.

(a) Unphysical cause on January 3rd, 01:20-01:30

(b) Physical cause on January 6th, 13:00-13:10

All in all we can say that the 5σ criterion is only an estimation of unusable values and relies on experience. By fixing the threshold to 5σ one states that all fluctuation within this interval are statistically significant. It implies reliability of the measurement system and is vulnerable to environmental influences, e.g. weather conditions.

6 Increment PDF

In this last task the aim was to compute the increment PDF. This probability density function defines the distribution of short term changes on the time axis. The formalism is $\delta u_\tau = u(t+\tau) - u(t)$ for a time lag of $\tau = 1s$. We collected the data in a histogram with 60 bins which gives a relatively smooth curve and normalized the values to unit standard deviation. We note that on this semi-logarithmic scale the relative frequencies of the 1sec-increments diverge clearly from the normal distribution. Extreme values for the 1s fluctuation are much more likely then a normal distribution suggests. In this case for increments of extreme values $\delta u = \pm 10m/s$ we observe a difference up to an order of magnitude 10^{17} between the probabilities according to Gauss and the actual relative frequencies derived from the measurement data. For small absolute values of δu the Normal

Figure 3: Increment PDF for $\tau = 1$ and Normal Distribution

Distribution overestimates the actual frequencies, but only to a maximal order of magnitude of 10^1 . Considering the IEC standards the assumption of a Gaussian PDF is not conservative and does not take into account the high probability of extreme fluctuations. This should be considered by industry when designing turbines regarding load analysis.
